## Abstract

This report presents the results from the investigations documenting after-effects of extreme flood events (major deviations in riparian hydrology) carried out in Mediterranean Spain in the EU FP7 project REFRESH. The investigations aimed to document how extreme winter flooding periods affect stream riparian wetlands. Results on wetland biogeochemistry (N and P), biodiversity (plants) and functioning (nutrient cycling) are presented.

### **Abstract**

The aim of this study was to examine temporal and spatial patterns of nitrous oxide (N<sub>2</sub>O) and carbon dioxide (CO<sub>2</sub>) fluxes across a Mediterranean riparian gradient under contrasting climatic conditions (flood and drought), and identify the environmental factors that controls this variability. Gas emissions were fortnightly measured from May 2011 to October 2012. Two years that differed in hydrological conditions: During spring of 2011 the riparian zone was entirely inundated after a 50-year recurrence flood; in contrast of 2012 that was relatively dry. The gas emissions were measured in situ using close chambers distributed at 18 sampling plots (40x40 cm) across the stream-riparian gradient based on differences in soil texture and dominant vegetation types. At each plot, we also measured soil moisture, temperature, REDOX, pH, soil nitrate, total C and N, organic matter debris, and % of grass coverage. The rate of N<sub>2</sub>O fluxes ranged from 0.5 to 8 µg N m<sup>-2</sup> h<sup>-1</sup>. The highest rates were measured in semi-inundated plots near the stream edge, whereas the lowest rates were measured uphill of the riparian zone. A contrasting pattern was observed for rates of CO<sub>2</sub> fluxes, which ranged from 0.2 to 20 g CO<sub>2</sub> m<sup>-2</sup> h<sup>-1</sup>. The lowest rates were measured at the stream edge, and the highest rates were measured uphill. However, both gas emissions showed a remarkable seasonal pattern with higher rates during the vegetative period, although we found high variability of fluxes between the two years, and with a contrast annual emission between the magnitude of CO<sub>2</sub> and N<sub>2</sub>O fluxes. During the wet year, spatial variability of gas emissions was mostly driven by soil moisture and REDOX, but during the dry year, there was a threshold at 20% of soil moisture for N<sub>2</sub>O emissions, while other factors (Organic matter, temperature, soil texture) additionally control the emission rates of the two gases.

**Abstract**

Hydrologic regime of Mediterranean streams is characterized by episodic floods and summer droughts. This high hydrological variability, especially associated with floods, modifies the physical, chemical and morphological characteristics of the stream, and affects the lateral hydrologic exchange between the stream and the riparian zone. This study aims to examine the hydrological and biogeochemical linkages between surface stream and the riparian groundwater under variable stream flow conditions. The study was done in Riera d'Arbúcies (NE Spain) from April 2001 to November 2012. In March a major flood occurred (14 m<sup>3</sup>/s). From September to October we induced an experimental drought to force expanding the range of hydrologic conditions, since this stream usually has permanent flow year round. We selected a 130-m reach in which we installed 24 piezometers which were distributed in 6 transects across the riparian zone. The discharge and morphology of the stream channel was measured weekly at 14 transects. We also collected water from the stream and from the wells, and measured water temperature, dissolved oxygen (DO), nutrient concentrations, and the water level elevation in the wells. The temporal variation in water table elevation showed a fast response to changes in stream discharge suggesting a strong hydrological linkage between the stream and the riparian zone that extended even at the furthest wells from the stream channel (c.a. 15 m into the riparian zone). Groundwater chemistry also showed considerable temporal variation following stream hydrologic conditions and changes were mostly related to REDOX conditions. Groundwater had higher DO and nitrate and lower ammonium concentrations at the beginning of the study than during the drought conditions.

12 **Abstract**

13 Hydrologic regime of Mediterranean streams is characterized by episodic floods  
14 and summer droughts. This high hydrological variability, especially associated  
15 with floods, modifies the physical, chemical and morphological characteristics of  
16 the stream, and affects the lateral hydrologic exchange between the stream and  
17 the riparian zone. This study aims to examine the hydrological and  
18 biogeochemical linkages between surface stream and the riparian groundwater  
19 under variable stream flow conditions. The study was done in Riera d'Arbúcies  
20 (NE Spain) from April 2011 to November 2012. In March of 2011 a major flood  
21 occurred ( $14 \text{ m}^3/\text{s}$ ). From September to October we induced an experimental  
22 drought to force expanding the range of hydrologic conditions, since this stream  
23 usually has permanent flow year round. We selected a 130-m reach in which we  
24 installed 24 piezometers which were distributed in 6 transects across the  
25 riparian zone. The discharge and morphology of the stream channel was

26 measured weekly at 14 transects. We also collected water from the stream and  
27 from the wells, and measured water temperature, dissolved oxygen (DO),  
28 nutrient concentrations, and the water level elevation in the wells. The temporal  
29 variation in water table elevation showed a fast response to changes in stream  
30 discharge suggesting a strong hydrological linkage between the stream and the  
31 riparian zone that extended even at the furthest wells from the stream channel  
32 (c.a. 15 m into the riparian zone). Groundwater chemistry also showed  
33 considerable temporal variation following stream hydrologic conditions and  
34 changes were mostly related to REDOX conditions. Groundwater had higher  
35 DO and nitrate and lower ammonium concentrations at the beginning of the  
36 study than during the drought conditions.

37

## 38 **Introduction**

39 The stream–riparian interface is the zone connecting the stream and the  
40 catchment and it has been defined as a spatially fluctuating ecotone between  
41 the surface stream and the deep groundwater (Boulton and others 1998).  
42 Consequently, several field studies have investigated the stream–riparian  
43 interface in regulating stream hydrology (McGlynn and McDonnell 2003;  
44 Butturini and others 2002) or biogeochemistry (Schindler and Krabbenhoft  
45 1998; Vidon and Hill 2004; Wigington and others 2003). In Mediterranean  
46 regions, the Hydrologic regime of Mediterranean streams is characterized by  
47 episodic floods and summer droughts. This high hydrological variability modifies  
48 the physical, chemical and morphological characteristics of the stream, and  
49 affects the lateral hydrologic exchange between the stream and the riparian  
50 zone (Gasith and Resh 1999). During drought conditions there is a disruption in

51 hydrological connectivity that ranges from flow reduction to loss of hydrologic  
52 connectivity between surface water, groundwater and the riparian zone (Lake  
53 2003). Recent studies in the Mediterranean adduce evidence of a severe  
54 alteration of precipitation and hydrological regimes and hypothesize an increase  
55 in the frequency of extreme events particularly in summer (Christensen and  
56 Christensen 2003; Schröter and others 2005). In this context, it is essential to  
57 assess how the stream riparian interface controls the transport and fate of  
58 nutrients that flow in Mediterranean freshwater ecosystems under the extreme  
59 effects of dry–wet hydrological shifts. During this transitional period between dry  
60 and wet conditions the hydrology of the stream–riparian interface is highly  
61 dynamic due to: (1) abrupt changes in groundwater levels; (2) occurrence of  
62 reverse fluxes in the subsurface stream–catchment interface; (3) rapid  
63 expansion and shrinkage of the boundary of the stream–catchment interface;  
64 (4) longer riparian groundwater flow-paths (Butturini and others 2003).  
65 Nevertheless, there is little information about the effect of the abrupt  
66 hydrological processes that take place in the stream riparian interface on  
67 reactivity and transport of nutrients from the riparian areas to the streams.  
68 Whilst some initial studies have been undertaken in Mediterranean streams  
69 covering the effect of the antecedent hydrological conditions on temporal  
70 dynamics and the fate of total DOC (Dissolved Organic Carbon) and discrete  
71 dissolved organic molecular fractions transported across the stream–riparian  
72 interface to improve our knowledge of the possible effect of altering the  
73 discharge pattern on stream DOC transport after abrupt hydrological shifts  
74 (Vazquez and others 2007).

76 Within this framework, our main objective is to explore the hydrological and  
77 biogeochemical linkages between surface stream and the riparian groundwater  
78 under the effects of extreme hydrological conditions (flood and drought). For  
79 this purpose, groundwater samples were collected from a wide Mediterranean  
80 riparian gradient during two years characterized by contrasting antecedent  
81 hydrological conditions. During spring of 2011 the riparian zone was entirely  
82 inundated after a 50-year recurrence flood; in contrast, 2012 was characterized  
83 by severe dry conditions. At some point the stream channel became completely  
84 dry in summer although this stream has usually permanent flow throughout the  
85 year. Therefore, we hypothesize that a change in discharge regime in  
86 Mediterranean regions, as a consequence of a warmer climate, might intensify  
87 more severe and dynamic hydrological processes at the stream–riparian  
88 interface, which might affect biogeochemical process occurring at the riparian  
89 zone and to have consequences on inputs of leaching of nutrients, especially  
90 nitrate, during flood episodes.

91

## 92 **Material and methods**

93

### 94 ***Study site***

95 The location of this study was situated in the low part of Riera de Arbucies, in  
96 La Tordera catchment (Catalonia, NE, Spain). This is a 4<sup>th</sup> order stream,  
97 tributary of the main river in the catchment, La Tordera. Climate of the Arbucies  
98 catchment can be classified as humid Mediterranean. Mean annual rainfall is  
99 more than 950 mm. Riera de Arbucies drains an area of 114km<sup>2</sup>. More than 50  
100 % of catchment area is occupied by forested zones and over 25 % is occupied

101 by agricultural and urban zones. Catchment is dominated by siliceous geology  
102 and its river bed is mainly composed by grains of quartz sand and fine gravels.  
103 The study site comprises a 120 m long and 20 m wide riparian zone. The  
104 vegetation of the site was basically grasses, hydrophytes and a few riparian  
105 trees and shrubs (*Salix sp* and *Populus sp*).

106

### 107 ***Water table level and precipitation***

108 Stretch was divided in two different zones: one upstream water (Up Zone) and  
109 one downstream water (Down Zone) (Figure 1). The selected reaches were  
110 homogeneous in altitude, topography variations and vegetation. A grid of  
111 dipwells was installed in each section across right shore riparian zone. Grids  
112 were composed by 4 rows of 3 piezometers each one. The distances from the  
113 stream were 1, 3, 7 and 15 m. These rows were named line 1, 2, 3 and 4  
114 respectively. Each piezometer consists in 32-mm diameter PVC. Wells were  
115 screened (4-5mm holes at 50 mm intervals) the last 40, 60 and 100 cm  
116 respectively. They were varied in length according to the location in the stream-  
117 riparian gradient (1 to 4m). The top of the wells were covered by a cap.  
118 Water table elevation was measured from July 2011 to October 2012 each 15  
119 days using a portable probe in each line. Complementary, in line 4 at each  
120 stretch, a continuous water level data logger (HOBO U-20, Onset) was installed  
121 at 20 min intervals to establish the elevation of the groundwater.

122 Precipitation data were provided by a meteorological station located 5 km from  
123 the study site.

124

### 125 ***Field sampling***

126 From July 2011 to October 2012, stream water and groundwater were sampled  
127 21 times, at least once a month. In order to do that, a peristaltic pump was  
128 used. Electrical Conductivity (EC), dissolve oxygen (D.O) and temperature were  
129 measured directly in the field. Prior to sampling and readings, wells were  
130 purged. All water samples were filtered in situ through glass microfiber filters  
131 and stored at -20°C until their analysis in the laboratory. SPR,  $\text{NO}_3^-$ ,  $\text{NO}_2^-$  and  
132  $\text{NH}_4^+$  were determined by standard colorimetric methods (APHA 1995) using an  
133 autoanalyser (Integral Futura, Alliance Instruments, Frépillon, France). In  
134 addition, stream discharge was measured every 15 days by performing a slug  
135 injection of sodium chloride used as a hydrological tracer (Gordon *et al*, 1992).

136

## 137 **Results**

138

### 139 ***Hydrological setting***

140 Discharge and groundwater level showed a clear response to the rainfall (Fig 2  
141 a-c). Just before the study started, a major flood, one in fifty years, happened.  
142 This flood raised 13, 7 m<sup>3</sup>. During the study, two big flood (December 2011 and  
143 October 2012) and an exceptional drought (August 2012) occurred. Maximum  
144 and minimum discharge were 4, 5 m<sup>3</sup> (25th December 2011) and 0,00 m<sup>3</sup>  
145 (whole August 2012) respectively.

146 In Fig 2 c, water table level is showed from line 4. It showed a clear relationship  
147 with rain, even 15 m far from the water channel. Groundwater increased its level  
148 when rains occurred and suffered a huge decrease during drought periods.  
149 Groundwater level in Line 4 varied from 0,5 m ( during flood events) to more  
150 than 2,5 m ( during drought event) depth from soil. Levels are corrected by

151 topography. Up and down zone groundwater levels presented differences. This  
152 difference was about 40 cm, according to the slope of the stretch (0, 3 cm/km).  
153 To have knowledge about the evolution of this disparity between both water  
154 levels, a temporal difference was performed (Up – Dw) and these new data was  
155 standardized by mean and standard deviation ( $x-\mu/\sigma$ ). Results are shown in Fig  
156 2-d. Negative values indicated periods when the difference between sections  
157 decreased (wet periods) and positive values indicated difference increase (dry  
158 periods). This variance shows an annual pattern: drought winter and summers  
159 and wet spring and autumn.

160 In order to determine different hydrological phases, four periods were  
161 determined using this hydrological variance. First period is called Sumer 2011  
162 and included summer and early autumn since they were the driest months  
163 during this year. Despite that fact, this summer was particularly wet and rains  
164 raised more than 200 mm. In particular this period included from 1<sup>st</sup> July 2011 to  
165 31<sup>st</sup> October 2011. Next period was defined as winter and it covered from 1<sup>st</sup>  
166 November 2011 to 31<sup>st</sup> March 2012. This period included both wet and dry  
167 periods and had 275 mm rain. Spring period lasted from 1<sup>st</sup> May 2012 to 15<sup>th</sup>  
168 July 2012. It was a wet period (155 mm) since rains in Mediterranean climate  
169 are concentrated in this season. Summer 2012 was defined from 16<sup>th</sup> July to  
170 30<sup>th</sup> September. It was a very dry summer, with less than 20 mm in more than 2  
171 months.

172

### 173 ***Water level profiles***

174 Water level across Stream Riparian Gradient showed differences between  
175 zones and periods (Fig 3). Summer 2011 was a wet summer in comparison with

176 summer 2012. Consequently in both zones, water level is higher in 2011 than in  
177 2012. In the two years, up and down zone had differences, since down profile  
178 had in both cases a steeper slope. That suggests that down zone is a losing  
179 stretch, discharging water into the aquifer during summer.

180 In both zones, winter period had the highest water level, due to winter rains and  
181 lack of vegetation evapotranspiration in the catchment. Spring period had very  
182 similar discharge, but the start of evapotranspiration created a decrease of  
183 groundwater level during this period.

184

### 185 ***Groundwater Chemistry Variation along SRG***

186 Annual data are shown in Figure 4. Each analyzed parameter showed a clear  
187 pattern along stream riparian gradient SRP (given as  $\text{PO}_4$ ) in the stream was  
188 similar to line 4. Meanwhile in lines 1, 2 and 3, SRP is higher. This pattern was  
189 showed in both sections. A similar pattern was found in  $\text{N-NH}_4$  concentration. In  
190 that case, concentration was higher in up zone than in down zone but always  
191 following the same pattern, with higher concentrations in riparian zone than in  
192 stream or riparian edge. In the other side, dissolve oxygen and  $\text{NH}_3$  showed and  
193 opposite pattern with lower concentration in the lines 1, 2 and 3 than in stream  
194 or line 4 water. Those patters are showed in both zones.  $\text{NH}_4$  and  $\text{NO}_3$  showed  
195 the same tendency in every period.

196

### 197 ***Discussion***

198 Our results show that the temporal variation in water table elevation confirms a  
199 fast response to changes in stream discharge suggesting a strong hydrological  
200 linkage between the stream and the riparian zone. Likewise, groundwater

201 chemistry proves considerable temporal variation following stream hydrologic  
202 conditions and changes related to REDOX conditions of the groundwater.  
203 Observed water level variations along the stream riparian gradient were mainly  
204 controlled by the adjacent stream discharge events and by the riparian water  
205 table fluctuations. Nevertheless, under natural conditions the hydrological  
206 regime of riparian areas often leads to large seasonal fluctuations in water table  
207 elevation. (Burt et al. 2002),
